Models in the bank

A model can be understood as a quantitative process that consumes inputs and produces estimates or classifications as an output. This is uncertain in nature.

- There is a variety of the models used in a bank. Examples are:
- Stress models (scenario-based stress losses)
- Financial crime detection,
- Pricing models,
- Marketing models,
- > Credit risk (PD, LGD, EAD)

0

What is a credit loss?

2

How to combine variables into credit rating?

We are interested in which of the variables' combination would imply the best risk assessment.

<u>General Linear Models (GLM):</u> each outcome Y of the dependent variables is assumed to be generated from a particular distribution in an exponential family, a large class of probability distributions. The mean μ of the distribution depends on the independent variables X through:

 $E(Y|X) = \mu = g^{-1}(X\beta)$

Where E(Y|X) is the expected value of Y conditional on X, $X\beta$ is a linear predictor, a linear combination of unknown parameters β , g is a link function.

We assume that:

- Y = 1, if an event occurred (e.g., default),
- Y = 0, if an event did not occur.

Examples of the link functions (g) – often used in practice:

Logistic function (logit)

CDF of the normal distribution (probit)

$$g(p) = \ln \left(\frac{p}{1-p} \right)$$

 $g(p) = \Phi^{-1}(p)$

What is a default?

1

Credit loss - example

Assume that a borrower XYZ takes out a \$400,000 loan for a condo. After making installment payments on the loan for a few years, the borrower faces financial difficulties and defaults when the loan has an outstanding balance, or exposure at default, of \$500,000. The bank forecloses on the condo and is able to sell it for \$240,000. What is the PD, LGD, EL and net loss to the bank?

- EAD =
- Net loss =
- PD =
- LGD =

Now, let's assume that we project out a **potential** but **not certain** loss. The expected loss would be different. Using the same figures from the scenario above, but assuming 50% probability of default in one year horizon, the expected loss is:

• EL = PD · EAD · LGD =

3

Measuring discriminatory power of the model (I/III)

Receiver operating characteristic (ROC) is a graphical plot that illustrates the diagnostic ability of a binary classifier system as its discrimination threshold is varied

 The ROC curve says how much the model is capable of distinguishing between classes. Higher the AUC (area under the curve = integral), better the model is at predicting 0s as 0s and 1s as 1s.

By example: higher the AUC, better the model is at distinguishing between clients who would default from those who will not.

- The ROC curve is plotted with TPR against the FPR where TPR is on y-axis and FPR is on the x-axis.
 - \circ TPR (True Positive Rate, sensitivity) = TP / (TP + FN)
 - Specificity = TN / (TN + FP)
 FPR = 1 Specificity = FP / (TN + FP)
 - FPR = 1 Specificity = FP / (TI
 Example confusion matrix:

| | Predicted: No default | Predicted: Default | |
|--------------------|--------------------------|-----------------------|------|
| Actual: No default | TN = 500 | FP = 10 | 510 |
| Actual: Default | FN = 20 | TP = 470 | 490 |
| | 520 | 480 | 1000 |
